HAMILTONICITY IN LOCALLY FINITE GRAPHS: TWO EXTENSIONS AND A COUNTEREXAMPLE

KARL HEUER

Abstract. We state a sufficient condition for the square of a locally finite graph to contain a Hamilton circle, extending a result of Harary and Schwenk about finite graphs.

We also give an alternative proof of an extension to locally finite graphs of the result of Chartrand and Harary that a finite graph not containing $K^4$ or $K_{2,3}$ as a minor is Hamiltonian if and only if it is 2-connected. We show furthermore that, if a Hamilton circle exists in such a graph, then it is unique and spanned by the 2-contractible edges.

The third result of this paper is a construction of a graph which answers positively the question of Mohar whether regular infinite graphs with a unique Hamilton circle exist.

1. Introduction

Results about Hamilton cycles in finite graphs can be extended to locally finite graphs in the following way. For a locally finite connected graph $G$ we consider its Freudenthal compactification $|G|$. This is a topological space obtained by taking $G$, seen as a 1-complex, and adding the ends of $G$, which are the equivalence classes of the rays of $G$ under the relation of being inseparable by finitely many vertices, as additional points. Extending the notion of cycles, we define circles in $|G|$ as homeomorphic images of the unit circle $S^1 \subseteq \mathbb{R}^2$ in $|G|$, and we call them Hamilton circles of $G$, if they contain all vertices of $G$. As a consequence of being a closed subspace of $|G|$, Hamilton circles also contain all ends of $G$. Following this notion we call $G$ Hamiltonian if there is a Hamilton circle in $|G|$.

One of the first and probably one of the deepest results about Hamilton circles was Georgakopoulos’s extension of Fleischner’s theorem to locally finite graphs.

Theorem 1.2. [14] Thm. 3] The square of any locally finite 2-connected graph is Hamiltonian.

Following this breakthrough, more Hamiltonicity theorems have been extended to locally finite graphs in this way [1 4 14 15 18 19 21].

The purpose of this paper is to extend two more Hamiltonicity results about finite graphs to locally finite ones and to construct a graph which shows that another result does not extend.

The first result we consider is a corollary of the following theorem of Harary and Schwenk. A caterpillar is a tree such that after deleting its leaves only a path is left. Let $S(K_{1,3})$ denote the graph obtained by taking the star with three leaves, $K_{1,3}$, and subdividing each edge once.

Theorem 1.3. [16] Thm. 1] Let $T$ be a finite tree with at least three vertices. Then the following statements are equivalent:

(i) $T^2$ is Hamiltonian.
(ii) $T$ does not contain $S(K_{1,3})$ as a subgraph.
(iii) $T$ is a caterpillar.

Theorem 1.3 has the following obvious corollary.

**Corollary 1.4.** \[15\] The square of any finite graph $G$ on at least three vertices such that $G$ contains a spanning caterpillar is Hamiltonian.

While the proof of Corollary 1.4 is immediate, the proof of the following extension of it, which is the first result of this paper, needs more work. We call the closure $\overline{H}$ in $|G|$ of a subgraph $H$ of $G$ a **standard subspace** of $|G|$. Extending the notion of trees, we define **topological trees** as topologically connected standard subspaces not containing any circles. As an analogue of a path, we define an arc as a homeomorphic image of the unit interval $[0, 1] \subseteq \mathbb{R}$ in $|G|$. Note that for standard subspaces being topologically connected is equivalent to being arc-connected by Lemma 2.4. For our extension we adapt the notion of a caterpillar to the space $|G|$ and work with **topological caterpillars**, which are topological trees $\overline{T}$ such that $\overline{T} - L$ is an arc, where $T$ is a forest in $G$ and $L$ denotes the set of vertices of degree 1 in $T$.

**Theorem 1.5.** The square of any locally finite connected graph $G$ on at least three vertices such that $|G|$ contains a spanning topological caterpillar is Hamiltonian.

The other two results of this paper concern the uniqueness of Hamilton circles. The first is about finite outerplanar graphs. These are finite graphs that can be embedded in the plane so that all vertices lie on the boundary of a common face. Clearly, finite outerplanar graphs have a Hamilton cycle if and only if they are 2-connected. It is also easy to see that any finite 2-connected outerplanar graph has a unique Hamilton cycle, which consists precisely of the 2-contractible edges, i.e., those edges each of whose contraction leaves the graph 2-connected (except for the case where the graph is a $K^3$), as pointed out by Syslo. We summarise this with the following proposition.

**Proposition 1.6.** (i) A finite outerplanar graph is Hamiltonian if and only if it is 2-connected.
(ii) \[26\] Thm. 6] Finite 2-connected outerplanar graphs have a unique Hamilton cycle, which consists precisely of the 2-contractible edges unless the graph is isomorphic to a $K^3$.

Finite outerplanar graphs can also be characterised by forbidden minors, which was done by Chartrand and Harary.

**Theorem 1.7.** \[6, Thm. 1\] A finite graph is outerplanar if and only if it contains neither a $K^4$ nor a $K_{2,3}$ as a minor.$^1$

In the light of Theorem 1.7 we first prove the following extension of statement (i) of Proposition 1.6 to locally finite graphs.

**Theorem 1.8.** Let $G$ be a locally finite connected graph. Then the following statements are equivalent:
(i) $G$ is 2-connected and contains neither $K^4$ nor $K_{2,3}$ as a minor.$^\dagger$
(ii) $|G|$ has a Hamilton circle $C$ and there exists an embedding of $|G|$ into a closed disk such that $C$ is mapped onto the boundary of the disk.

Furthermore, if statements (i) and (ii) hold, then $|G|$ has a unique Hamilton circle.

From this we then obtain the following corollary, which extends statement (ii) of Proposition 1.6.$^1$

\[1\] Actually these statements can be strengthened a little bit by replacing the part about not containing a $K^4$ as a minor by not containing it as a subgraph. This follows from Lemma 4.1.
Corollary 1.9. The edges contained in the Hamilton circle of a locally finite 2-connected graph not containing \( K^4 \) or \( K_{2,3} \) as a minor are precisely the 2-contractible edges of the graph unless the graph is isomorphic to a \( K^3 \).

We should note here that parts of Theorem 1.8 and Corollary 1.9 are already known. Chan [5, Thm. 20 with Thm. 27] proved that a locally finite 2-connected graph not containing \( K^4 \) or \( K_{2,3} \) as a minor has a Hamilton circle that contains the 2-contractible edges of the graph, but no further ones. He deduces this from other general results about 2-contractible edges in locally finite 2-connected graphs. In our proof, however, we directly construct the Hamilton circle and show its uniqueness without working with 2-contractible edges. Afterwards, we deduce Corollary 1.9.

Our third result is related to the following conjecture Sheehan made for finite graphs.

Conjecture 1.10. For every \( r > 2 \) there is no finite \( r \)-regular graph with a unique Hamilton cycle.

This conjecture is still open, but some partial results have been proved [17, 28, 29]. For \( r = 3 \) the statement of the conjecture was verified by Smith first. This was noted in an article of Tutte [30] where the statement for \( r = 3 \) was published for the first time.

For infinite graphs Conjecture 1.10 is not true in this formulation. It fails already with \( r = 3 \). To see this consider the graph depicted in Figure 1, called the double ladder.

![Figure 1. The double ladder](image)

It is easy to check that the double ladder has a unique Hamilton circle, but all vertices have degree 3. Mohar has modified the statement of the conjecture and raised the following question. To state them we need to define two terms. For a graph \( G \) we call the equivalence classes of rays under the relation of being inseparable by finitely many vertices the ends of \( G \). We define the vertex- or edge-degree of an end \( \omega \) to be the supremum of the number of vertex- or edge-disjoint rays in \( \omega \), respectively. In particular, ends of a graph \( G \) can have infinite degree even if \( G \) is locally finite.

Question 1. Does an infinite graph exist that has a unique Hamilton circle and degree \( r > 2 \) at every vertex as well as vertex-degree \( r \) at every end?

Our result shows in contrast to Conjecture 1.10 and its known cases that there are infinite graphs having the same degree at every vertex and end while being Hamiltonian in a unique way.

Theorem 1.11. There exists an infinite connected graph \( G \) with a unique Hamilton circle that has degree 3 at every vertex and vertex- as well as edge-degree 3 at every end.

So with Theorem 1.11 we answer Question 1 positively and therefore disprove the modified version of Conjecture 1.10 for infinite graphs in the way Mohar suggested by considering degrees of both vertices and ends.
The rest of this paper is structured as follows. In Section 2 we establish the notation and terminology we need for the rest of the paper. We also list some lemmas that will serve as auxiliary tools for the proofs of the main theorems. Section 3 is dedicated to Theorem 1.5 where at the beginning of that section we discuss how one can sensibly extend Corollary 1.3 and which problems arise when we try to extend Theorem 1.3 in a similar way. In Section 4 we present a proof of Theorem 1.8 and describe afterwards how a different proof of this theorem works that is copying the ideas of a proof of statement (i) of Proposition 1.6. The last section, Section 5, contains the construction of a graph witnessing Theorem 1.11.

2. Preliminaries

When we mention a graph in this paper we always mean an undirected and simple graph. For basic facts and notation about finite as well as infinite graphs we refer the reader to [7]. For a broader survey about locally finite graphs and a topological approach to them see [8].

Now we list important notions and concepts that we shall need in this paper followed by useful statements about them. In a graph $G$ with a vertex $v$ we denote by $\delta(v)$ the set of edges incident with $v$ in $G$. Similar for a subgraph $H$ of $G$ or just its vertex set we denote by $\delta(H)$ the set of edges that have only one endvertex in $H$. Although formally different, we will not always distinguish between a cut $\delta(H)$ and the partition $(V(H), V(G) \setminus V(H))$ it is induced by. For two vertices $v, w \in V(G)$ let $d_G(v, w)$ denote the distance between $v$ and $w$ in $G$.

We call a finite graph outerplanar if it can be embedded in the plane such that all vertices lie on the boundary of a common face.

For a graph $G$ and an integer $k \geq 2$ we define the $k$-th power of $G$ as the graph obtained by taking $G$ and adding additional edges $vw$ for any two vertices $v, w \in V(G)$ such that $1 < d_G(v, w) \leq k$.

A tree is called a caterpillar if after the deletion of its leaves only a path is left. We denote by $S(K_{1,3})$ the graph obtained by taking the star with three leaves $K_{1,3}$ and subdividing each edge once.

We call a graph locally finite if each vertex has finite degree.

A one-way infinite path in a graph $G$ is called a ray of $G$, while we call a two-way infinite path in $G$ a double ray of $G$. An equivalence relation can be defined on the set of rays of a graph $G$ by saying that two rays are equivalent if and only if they cannot be separated by finitely many vertices in $G$. The equivalence classes of this relation are called the ends of $G$.

For a locally finite and connected graph $G$ we can endow $G$ together with its ends with a topology that yields the space $|G|$. A precise definition of $|G|$ can be found in [7, Ch. 8.5]. Let us point out here that a ray of $G$ converges in $|G|$ to the end of $G$ if it is contained in another way of describing $|G|$ is to endow $G$ with the topology of a 1-complex and then forming the Freudenthal compactification [11].

For a point set $X$ in $|G|$, we denote its closure in $|G|$ by $\overline{X}$. We shall often write $\overline{M}$ for some $M$ that is a set of edges or a subgraph of $G$. In this case we implicitly assume to first identify $M$ with the set of points in $|G|$ which corresponds to the edges and vertices that are contained in $M$.

We call a subspace $Z$ of $|G|$ standard if $Z = \overline{H}$ for a subgraph $H$ of $G$.

A circle in $|G|$ is the image of a homeomorphism having the unit circle $S^1$ in $\mathbb{R}^2$ as domain and mapping into $|G|$. Note that all finite cycles of a locally finite graph $G$ correspond to circles in $|G|$, but there might also be infinite subgraphs $H$ of $G$ such that $\overline{H}$ is a circle in $|G|$. Similar to finite graphs we call a locally finite graph $G$ Hamiltonian if there exists a circle in $|G|$ which contains all vertices of $G$. Such circles are called Hamilton circles of $G$. 
We call the image of a homeomorphism with the closed real unit interval \([0, 1]\) as domain and mapping into \(|G|\) an arc in \(|G|\). Given an arc \(a\) in \(|G|\), we call a point \(x\) of \(|G|\) an endpoint of \(a\) if 0 or 1 is mapped to \(x\) by the homeomorphism defining \(a\). Similar as for paths, we call an arc an \(x\)-\(y\) arc if \(x\) and \(y\) are the endpoints of the arc. The possibly simplest example of a nontrivial arc is a ray together with the end it converges to. However, the structure of arcs is more complicated in general and they might contain up to \(2^\omega\) many ends. We call a subspace \(X\) of \(|G|\) arc-connected if for any two points \(x\) and \(y\) of \(X\) there is an \(x\)-\(y\) arc in \(X\).

Using the notions of circles and arc-connectedness we now extend trees in a similar topological way. We call an arc-connected standard subspace of \(|G|\) a topological tree if it does not contain any circle. Generalizing the definition of caterpillars, we call a topological tree \(T\) in \(|G|\) a topological caterpillar if \(T - L\) is an arc, where \(T\) is a forest in \(G\) and \(L\) denotes the set of all leaves of \(T\), i.e., vertices of degree 1 in \(T\).

Now let \(\omega\) be an end of a locally finite graph \(G\). We define the vertex- or edge-degree of \(\omega\) in \(G\) as the supremum of the number of vertex- or edge-disjoint rays in \(G\), respectively, which are contained in \(\omega\). By this definition ends may have infinite vertex- or edge-degree. Similar we define the vertex- or edge-degree of \(\omega\) in a standard subspace \(X\) of \(|G|\) as the supremum of vertex- or edge-disjoint arcs in \(X\), respectively, that have \(\omega\) as an endpoint. We should mention here that the supremum is actually an attained maximum in both definitions. Furthermore, these definitions coincide when we take \(X = |G|\). The proofs of these statements are nontrivial and since it is enough for us to work with the supremum, we will not go into detail here.

We make one last definition with respect to end degrees which allows us to distinguish the parity of degrees of ends when they are infinite. The idea of this definition is due to Bruhn and Stein [3]. We call the vertex- or edge-degree of an end \(\omega\) of \(G\) in a standard subspace \(X\) of \(|G|\) even if there is a finite set \(S \subseteq V(G)\) such that for every finite set \(S' \subseteq V(G)\) with \(S \subseteq S'\) the maximum number of vertex- or edge-disjoint arcs in \(X\), respectively, whose endpoints are \(\omega\) and some \(s \in S'\) is even. Otherwise, we call the vertex- or edge-degree of \(\omega\) in \(X\), respectively, odd.

Next we collect some useful statements about the space \(|G|\) for a locally finite graph \(G\).

**Proposition 2.1.** [7, Prop. 8.5.1] If \(G\) is a locally finite connected graph, then \(|G|\) is a compact Hausdorff space.

Having Proposition 2.1 in mind the following basic lemma helps us to work with continuous maps and verify homeomorphisms, for example when considering circles or arcs.

**Lemma 2.2.** Let \(X\) be a compact space, \(Y\) be a Hausdorff space and \(f : X \to Y\) be a continuous injection. Then \(f^{-1}\) is continuous too.

The following lemma tells us an important combinatorial property of arcs. To state the lemma more easily, let \(F\) denote the set of inner points of edges \(e \in F\) in \(|G|\) for an edge set \(F \subseteq E(G)\).

**Lemma 2.3.** [7, Lemma 8.5.3] Let \(G\) be a locally finite connected graph and \(F \subseteq E(G)\) be a cut with sides \(V_1\) and \(V_2\).

(i) If \(F\) is finite, then \(V_1 \cap V_2 = \emptyset\), and there is no arc in \(|G|\) \(\backslash \hat{F}\) with one endpoint in \(V_1\) and the other in \(V_2\).

(ii) If \(F\) is infinite, then \(V_1 \cap V_2 \neq \emptyset\), and there may be such an arc.
The next lemma ensures that connectedness and arc-connectedness are equivalent for the spaces we are mostly interested in, namely standard subspaces, which are closed by definition.

**Lemma 2.4.** [12, Thm. 2.6] If $G$ is a locally finite connected graph, then every closed topologically connected subset of $|G|$ is arc-connected.

Continuing with the idea of Lemma 2.3 of characterising important topological properties of the space $|G|$ in terms of combinatorial ones, the following lemma about arc-connected subspaces was obtained, which will be convenient for us to use in a proof later on.

**Lemma 2.5.** [7, Lemma 8.5.5] If $G$ is a locally finite connected graph, then a standard subspace of $|G|$ is topologically connected (equivalently: arc-connected) if and only if it contains an edge from every finite cut of $G$ of which it meets both sides.

The next theorem is actually part of a bigger one containing more equivalent statements. Since we shall need only one equivalence, we reduced it to the following formulation. For us it will be helpful to check or at least bound the degree of an end in a standard subspace just by looking at finite cuts instead of dealing with the homeomorphisms that actually define the relevant arcs.

**Theorem 2.6.** [8, Thm. 2.5] Let $G$ be a locally finite connected graph. Then the following are equivalent for $D \subseteq E(G)$:

(i) $D$ meets every finite cut in an even number of edges.

(ii) Every vertex and every end of $G$ has even degree or edge-degree in $D$, respectively.

The following lemma gives us a nice combinatorial description of circles and will be useful especially in combination with Theorem 2.6 and Lemma 2.5.

**Lemma 2.7.** [3, Prop. 3] Let $C$ be a subgraph of a locally finite connected graph $G$. Then $C$ is a circle if and only if $C$ is topologically connected and every vertex or end $x$ of $G$ with $x \in C$ has degree or edge-degree 2 in $C$, respectively.

We obtain the following corollary, which is a basic fact for finite graphs.

**Corollary 2.8.** Every locally finite connected Hamiltonian graph is 2-connected.

**Proof.** Let $G$ be a locally finite connected Hamiltonian graph and suppose for a contradiction that it is not 2-connected. Fix a subgraph $C$ of $G$ whose closure $\overline{C}$ is a Hamilton circle of $G$ and a cut vertex $v$ of $G$. Let $K_1$ and $K_2$ be two different components of $G - v$. By Theorem 2.6 the circle $\overline{C}$ uses evenly many edges of each of the finite cuts $\delta(K_1)$ and $\delta(K_2)$. Since $\overline{C}$ is a Hamilton circle and therefore topologically connected, we get also that it uses at least two edges of each of these cuts by Lemma 2.5. This implies that $v$ has degree at least 4 in $\overline{C}$ which contradicts Lemma 2.7. $\square$

### 3. Topological caterpillars

In this section we close a gap with respect to the general question when the $k$-th power of a graph has a Hamilton circle. Let us begin by summarizing the results in this field. We start with finite graphs. The first result to mention is the famous theorem of Fleischner, Theorem 1.1, which deals with 2-connected graphs.

For higher powers of graphs the following theorem captures the whole situation.

**Theorem 3.1.** [20, 21] The cube of any finite connected graph on at least three vertices is Hamiltonian.
These theorems leave the question whether and when one can weaken the assumption of being 2-connected and still maintain the property of being Hamiltonian. Theorem 1.3 gives an answer to this question.

Now let us turn our attention towards locally finite infinite graphs. As mentioned in the introduction, Georgakopoulos has completely generalized Theorem 1.1 to locally finite graphs by proving Theorem 1.2. Furthermore, he also gave a complete generalization of Theorem 3.1 to locally finite graphs with the following theorem.

**Theorem 3.2.** [14, Thm. 5] The cube of any locally finite connected graph on at least three vertices is Hamiltonian.

What is left and what we do in the rest of this section is to prove lemmas about locally finite graphs covering implications similar to those in Theorem 1.3, and mainly Theorem 1.5, which extends Corollary 1.4 to locally finite graphs. Note first that Theorem 1.3 remains true if we consider locally finite infinite trees \( T \) and Hamilton circles in \(|T^2| \) where the definition of a caterpillar should now include rays and double rays. Actually the same proof can be used to show this.

Corollary 1.4 is also true for locally finite graphs, but its proof is not trivial anymore. The problem is that for a spanning tree \( T \) of a locally finite connected graph \( G \) the topological spaces \(|T^2| \) and \(|G^2| \) might differ not only in inner points of edges but also in ends. More precisely, there might be two equivalent rays in \( G^2 \) that belong to different ends of \( T^2 \). So the Hamiltonicity of \( T^2 \) does not directly imply the one of \( G^2 \). However, for \( T \) being a spanning caterpillar of \( G \), this problem can only occur when \( T \) contains a double ray such that all subrays belong to the same end of \( G \). Then the same construction as in the proof for the implication from (iii) to (i) of Theorem 1.3 can be used to build a spanning double ray in \( T^2 \) which ends up being a Hamilton circle in \(|G^2| \). The idea for the construction which is used for this implication is covered in Lemma 3.4.

For an infinite graph the assumption of having a spanning caterpillar is quite restrictive. Such graphs can especially have at most two ends since having three ends would imply that the spanning caterpillar must contain three disjoint rays, which is impossible because it would force the caterpillar to contain a \( S(K_{1,3}) \). For this reason we have defined a topological version of a caterpillar, which allows graphs with arbitrary many ends to have a spanning one and yields with Theorem 1.5 an extension of Corollary 1.4 for locally finite graphs. We recall the definition of a topological caterpillar \( T \) being a topological tree such that \( T - L \) is an arc, where \( T \) is a forest in \( G \) and \( L \) denotes the set of all leaves of \( T \), i.e., vertices of degree 1 in \( T \).

The following basic lemma about topological caterpillars is easy to show and so we omit its proof. It is an analogue of the equivalence of the statements (ii) and (iii) of Theorem 1.3 for topological caterpillars.

**Lemma 3.3.** A topological tree \( T \) is a caterpillar if and only if \( T \) does neither contain \( S(K_{1,3}) \) as a subgraph nor an end of vertex-degree at least 3 in it.

Note that we do not get a full extension of Theorem 1.3 to locally finite graphs because \(|T^2| \) has a Hamilton circle if and only if \( T \) is a topological caterpillar with at most two ends, as noted above.

We continue with another basic lemma, which covers the idea of the proof that statement (iii) of Theorem 1.3 implies statement (i) of Theorem 1.3. We shall also need this in the proof of Theorem 1.5.

**Lemma 3.4.** Let \( T \) be a topological caterpillar in \(|G| \) for a locally finite connected graph \( G \). Then there exists a partition of the vertices of \( T \) and a linear order \(<_T \) of the partition classes such that:
(i) Any two different vertices belonging to the same partition class have distance 2 from each other in $T$.

(ii) For consecutive partition classes $Q$, $R$ and $S$ with $Q <_T R <_T S$ there is a unique vertex in $Q$ that is not a leaf of $T$ and has distance 2 to every vertex of $S$.

Proof. If $T$ has only two vertices, the statement is obvious. So we may assume that $T$ has at least three vertices. Let $L$ be the set of leaves of $T$. We know by definition that $T - L$ is an arc $A$. This arc induces a linear order $<_A$ of the vertices of $V(T) - L$. Using this linear order we define the desired partition of $V(T)$. For consecutive vertices $v, w \in V(T) - L$ with $v <_A w$ we define the set $P_{vw} = \{w\} \cup (N_T(v) \cap L)$ (cf. Figure 2). If $A$ has a maximal element $m$ with respect to $<_A$, we define an additional set $P^+ = N_T(m) \cap L$. Should $A$ have a minimal element $s$ with respect to $<_A$, we define another additional set $P^- = \{s\}$. By definition of topological caterpillars, the sets $P_{vw}$ together with $P^+$ and $P^-$ form a partition of $V(T)$ where all vertices in a partition class have distance 2 in $T$. This proves part (i).

Note for statement (ii) that the linear order $<_A$ induces a linear order $<_T$ on the partition classes in the following way. For vertices $v, w \in V(T) - L$ with $v <_A w$ set $P_v <_T P_w$. If $P^+$ (resp. $P^-$) exists, set $P_v <_T P^+$ (resp. $P^- <_T P_v$) for every $v \in V(T) - L$. Now the definition of the partition classes ensures that for consecutive partition classes $P_u, P_v$ and $P_w$ with $P_u <_T P_v <_T P_w$ the vertex $u$ has distance 2 in $T$ to every vertex of $P_w$. For $P_u = P^-$ the same is true with the unique vertex $s \in P^-$ by definition. □

![Figure 2. Partition classes as in Lemma 3.4](image_url)

Referring to statement (ii) of Lemma 3.4 let us call the vertex in a partition class that is not a leaf of $T$ the *jumping vertex* of $Q$.

We still need a bit of notation and preparation work before we can prove the main theorem of this section.

Let $T$ be a topological spanning caterpillar of a locally finite graph $G$. Next take a partition and a linear order $<_T$ on its classes as in Lemma 3.4. For a vertex $v \in V(G)$ let $\pi_v$ be the partition class containing $v$. For two vertices $v, w \in V(G)$ with $V_v \leq_T V_w$ let $I_{vw} = \bigcup\{V_u : V_v \leq_T V_u \leq_T V_w\}$.

Now let $T$ denote a topological caterpillar with only one graph-theoretical component. Let $(\mathcal{X}_1, \mathcal{X}_2)$ be a bipartition of the partition classes $V_v$ such that consecutive classes with respect to $\leq_T$ lie not both in $\mathcal{X}_1$ or $\mathcal{X}_2$. Furthermore, let $v, w \in V(T)$ be two vertices, say with $V_v \leq_T V_w$, whose distance is even in $T$. We define a $(v, w)$ square string in $T^2$ as a path in $T^2$ which uses only vertices of partitions that lie in the bipartition class $\mathcal{X}_i$ in which $V_v$ and $V_w$ lie and which contains all vertices of partition classes $V_v \in \mathcal{X}_i$ for $V_v <_T V_u <_T V_w$, but only $v$ and $w$ from $V_v$ and $V_w$, respectively. Similarly, we define $(v, w], [v, w)$ and $[v, w]$ square strings in $T^2$, but with the difference that they should also contain all vertices of $V_u, V_v$ and $V_w \cup V_v$, respectively. We call the first two types of square strings that were defined left open and the latter ones left closed. The notion of being right open and right closed is analogously defined. Lemma 3.4 contains the idea of how to construct square strings.
The next lemma gives us two possibilities to decompose a graph-theoretical component of a topological caterpillar \( \overline{T} \) that contains a double ray into two, possibly infinite, paths of \( T^2 \). Later on we will use these decompositions to connect the parts of all graph-theoretical components of \( \overline{T} \) in a certain way such that a Hamilton circle of \( G^2 \) is formed in the end.

**Lemma 3.5.** For a locally finite connected graph \( G \), let \( \overline{T} \) be a topological caterpillar in \(|G|\) with only one graph-theoretical component and which contains a double ray. Furthermore, let \( v \) and \( w \) be vertices of \( T \) with \( V_v \leq_T V_w \).

(i) If \( d_{T}(v, w) \) is even, then \( V(T) \) can disjointly be decomposed into a \( v-w \) path and a double ray of \( T^2 \) as well as into two rays \( R_v \) and \( R_w \) of \( T^2 \) with endvertices \( v \) and \( w \), respectively, such that \( R_v \cap V_x = \emptyset \) for every \( V_x >_T V_w \) and \( R_w \cap V_y = \emptyset \) for every \( V_y <_T V_v \).

(ii) If \( d_{T}(v, w) \) is odd, then \( V(T) \) can disjointly be decomposed into two rays \( R_v \) and \( R_w \) of \( T^2 \) with endvertices \( v \) and \( w \), respectively, such that \( R_v \cap V_x = \emptyset \) for every \( V_x >_T V_w \) and \( R_w \cap V_y = \emptyset \) for every \( V_y <_T V_v \) as well as into two rays \( R_v \) and \( R_w \) of \( T^2 \) with endvertices \( v \) and \( w \), respectively, such that \( R_v \cap V_x = \emptyset \) for every \( V_x >_T V_w \) and \( R_w \cap V_y = \emptyset \) for every \( V_y >_T V_v \).

**Proof.** We sketch the proof of statement (i). As \( v-w \) path for the first decomposition, we take a square string \( S_{vw} \) in \( T^2 \) with \( v \) and \( w \) as endvertices. Depending whether \( v \) is a jumping vertex or not we take a left open or closed square string, respectively. Depending on \( w \) we take a right closed or open square string if \( w \) is a jumping vertex or not, respectively. Since \( d_{T}(v, w) \) is even, we can find such square strings. To construct a corresponding double ray start with a \((v^-, w^-)\) square string in \( T^2 \) where \( v^- \) and \( w^- \) denote the jumping vertices in the partition classes proceeding \( V_v \) and \( V_w \), respectively. Using Lemma 3.4 the \((v^-, w^-)\) square string can be extend to a desired double ray containing all vertices of \( T \) that do not lie in \( S_{vw} \).

For the second decomposition, we start for the definition of \( R_v \) with a square string \( S_v \) having \( v \) as one endvertex. For the definition of \( S_w \) we distinguish four cases. If \( v \) and \( w \) are jumping vertices, we set \( S_v \) as a path obtained by taking a \((v, w)\) square string and deleting \( w \) from it. If \( v \) is not a jumping vertex, but \( w \) is one, take a \([v, w]\) square string, delete \( w \) from it and set the remaining path as \( S_v \). In the case that \( v \) is a jumping vertex, but \( w \) is none, \( S_v \) is defined as a path obtained from a deleting \( w \) from a \((v, w)\) square string. In the case that neither \( v \) nor \( w \) is a jumping vertex, we take a \([v, w]\) square string, delete \( w \) from it and set the remaining path as \( S_v \). Next we extend \( S_v \), using a square string to a path with \( v \) as one endvertex, containing all vertices in partition classes \( V_u \) with \( V_u <_T V_v <_T V_w \). We extend the remaining path to a ray that contains also all vertices in partition classes \( V_u \) with \( V_u <_T V_v \), but none from partition classes \( V_x \) for \( V_x >_T V_w \). The desired second ray \( R_v \cup R_w \) can now easily be build in \( T^2 - R_v \).

The decompositions for statement (ii) are defined in a very similar way (cf. Figure 3). Therefore, we omit their definitions here.

The following lemma is essential for connecting parts of decomposed graph-theoretical components of \( \overline{T} \). Especially, here we make use of the structure of \(|G|\) instead of arguing only inside of \( \overline{T} \). This allows us basically to build a Hamilton circle using square strings and to “jump over” an end to avoid producing an edge-degree bigger than 2 at that end.

**Lemma 3.6.** Let \( \overline{T} \) be a topological spanning caterpillar of a locally finite connected graph \( G \) and \( v, w \in V(G) \) where \( V_v \leq_T V_w \). Then for any two vertices \( x, y \) with \( V_x <_T V_v <_T V_w \) and \( V_v <_T V_y <_T V_w \) there exists an \( x-y \) path in \( G[I_{vw}] \).
Figure 3. Examples for decompositions as in Lemma 3.5

Proof. Let the vertices \(v, w, x\) and \(y\) be as in the statement of the lemma. Now suppose for a contradiction that there is no \(x-y\) path in \(G[I_{vw}]\). Then we can find an empty cut \(D\) of \(G[I_{vw}]\) with sides \(L\) and \(R\) such that \(x\) and \(y\) lie on different sides of it. Since \(\overline{T} \cap G[I_{vw}]\) contains an \(x-y\) arc, there must exist an end \(\omega \in \overline{T} \cap \overline{R}\). By definition, \(\overline{T}\) contains an arc with all vertices of \(G\) that are no leaves in \(T\), and every vertex of \(T\) is only adjacent to finitely many leaves, because \(G\) is locally finite. Therefore, we can find an open set \(O\) in \(|G|\) containing \(\omega\), but no vertex of \(V(G) \setminus I_{vw}\). Inside \(O\) we can find a basic open set \(B\) around \(\omega\), which contains a graph-theoretical connected subgraph with all vertices of \(B\). Now \(B\) contains vertices of \(R\) and \(L\) as well as a path between them, which must then also exist in \(G[I_{vw}]\). Such a path would have to cross \(D\) contradicting the assumption that \(D\) is an empty cut in \(G[I_{vw}]\). □

To figure out which parts of which decomposed graph-theoretical components of \(T\) we can connect such that afterwards we are still able to extend this construction to a Hamilton circle of \(G\), we shall use the next lemma. For the formulation of the lemma, we use the notion of \textit{splits}.

Let \(G\) be a multigraph and \(v \in V(G)\). Furthermore, let \(E_1, E_2 \subseteq \delta(v)\) such that \(E_1 \cup E_2 = \delta(v)\) where \(E_i \neq \emptyset\) for \(i \in \{1, 2\}\). Now we call a multigraph \(G'\) a \textit{v-split} of \(G\) if

\[
V(G') = V(G) \setminus \{v\} \cup \{v_1, v_2\}
\]

with \(v_1, v_2 \not\in V(G)\) and

\[
E(G') = E(G-v) \cup \{v_1w; \ w \in E_1\} \cup \{v_2u; \ u \in E_2\}.
\]

We call the vertices \(v_1\) and \(v_2\) replacement vertices of \(v\).

\textbf{Lemma 3.7.} Let \(G\) be a finite Eulerian multigraph and \(v\) be a vertex of degree 4 in \(G\). Then there exist two \(v\)-splits \(G_1\) and \(G_2\) of \(G\) which are Eulerian too.

\textit{Proof.} There are \(\frac{1}{2} \cdot \binom{4}{2} = 3\) possible non-isomorphic \(v\)-splits of \(G\) such that \(v_1\) and \(v_2\) have degree 2 in the \(v\)-split. Assume that one of them, call it \(G'\), is not Eulerian. This can only be the case if \(G'\) is not connected. Let \((A, B)\) be an empty cut of \(G'\). Note that \(G-v\) has precisely two components \(C_1\) and \(C_2\) since \(G\) is Eulerian and \(v\) has degree 4 in \(G\). So \(C_1\) and \(C_2\) must lie in different sides of \((A, B)\), say \(C_1 \subseteq A\). Since \(G\) was connected, we get that \(v_1\) and \(v_2\) lie in different
sides of the cut \((A, B)\), say \(v_1 \in A\). Therefore, \(A = C_1 \cup \{v_1\}\) and \(B = C_2 \cup \{v_2\}\). If \(d(v) = \{wv_1, wv_2, vw_2, vw_3, v_1v_2, v_2w_3, wv_3\}\) and \(\{v_1w_1, v_1w_2\}, \{v_2w_3, v_2w_4\} \subseteq E(G')\), set \(G_1\) and \(G_2\) as \(v\)-splits of \(G\) such that the inclusions \(\{v_1w_1, v_1w_3\}, \{v_2w_2, v_2w_4\} \subseteq E(G_1)\) and \(\{v_1w_1, v_1w_4\}, \{v_2w_2, v_2w_3\} \subseteq E(G_2)\) hold. Now \(G_1\) and \(G_2\) are Eulerian, because every vertex has even degree in each of those multigraphs and both multigraphs are connected. To see the latter statement, note that any empty cut \((X, Y)\) of \(G_i\) for \(i \in \{1, 2\}\) would need to have \(C_1\) and \(C_2\) on different sides. If also \(v_1\) and \(v_2\) are on different sides, we would have \((A, B) = (X, Y)\), which does not define an empty cut of \(G_i\) by definition of \(G_i\). But having \(v_1\) and \(v_2\) on the same side of the cut \((X, Y)\), this would induce an empty cut in \(G\) after identifying \(v_1\) and \(v_2\) in \(G_i\) and yield a contradiction to the assumption that \(G\) is Eulerian and therefore especially connected.

\(\square\)

Now we have all tools together to prove Theorem 1.5.

**Proof of Theorem 1.5.** Let \(G\) be a graph as in the statement of the theorem and let \(T\) be a topological spanning caterpillar of \(G\). We fix a partition of \(V(G)\) and an order \(\leq_T\) on it as in Lemma 3.4 with respect to \(T\) where \(V_i\) shall denote the partition class containing a vertex \(v \in V(G)\). We may assume by Corollary 1.4 that \(G\) has infinitely many vertices. Now let us fix an enumeration of the vertices, which is possible since every locally finite connected graph is countable. We build a Hamilton circle of \(G^2\) inductively in at most \(\omega\) many steps where we have two disjoint arcs \(\overline{AT}\) and \(\overline{BT}\) in \(|G^2|\) in each step \(i \in \mathbb{N}\) whose endpoints are vertices of subgraphs \(A_i\) and \(B_i\) of \(G^2\), respectively. Let \(a_i^1\) and \(a_i^2\) (resp. \(b_i^1\) and \(b_i^2\)) denote the endvertices of \(\overline{AT}\) (resp. \(\overline{BT}\)) such that \(V(a_i^1) \leq_T V(a_i^2)\) (resp. \(V(b_i^1) \leq_T V(b_i^2)\)). For the construction we ensure the following properties in each step \(i \in \mathbb{N}\):

1. The vertices \(a_i^1\) and \(b_i^1\) are the jumping vertices of \(V(a_i^1)\) and \(V(b_i^1)\), respectively.
2. The partition sets \(V(a_i^1)\) and \(V(b_i^1)\) as well as \(V(a_i^2)\) and \(V(b_i^2)\) are consecutive with respect to \(\leq_T\).
3. If \(V(a_i^1) \cap V(A_i \cup B_i) \neq \emptyset\) holds for any vertex \(v \in V(G)\), then \(V(a_i^1) \subseteq V(A_i \cup B_i)\).
4. If for any vertex \(v \in V(G)\) there are vertices \(u, w \in V(G)\) such that \(V(a_i^1) \subseteq V(A_i \cup B_i)\) and \(V(w) \leq_T V(u) \leq_T V(w)\), then \(V(a_i^1) \subseteq V(A_i \cup B_i)\) is true.
5. \(A_i \cap A_i^{i+1} = A_i^i\) and \(B_i \cap B_i^{i+1} = B_i^i\), but \(V(A_i^{i+1} \cup B_i^{i+1})\) contains the least vertex with respect to the fixed vertex enumeration that was not already contained in \(V(A_i \cup B_i)\).

We start the construction by picking two adjacent vertices \(t\) and \(t'\) in \(T\) that are no leaves in \(T\). Then \(V(t)\) and \(V(t')\) are consecutive with respect to \(\leq_T\). Since \(G^2[V]\) and \(G^2[V]\) are cliques by statement (i) of Lemma 3.4, we set \(A_1^1\) to be a Hamilton path of \(G^2[V]\) with endvertex \(t\) and \(B_1^1\) to be one of \(G^2[V]\) with endvertex \(t'\). This completes the first step of the construction.

Suppose we have already constructed \(A^n\) and \(B^n\). Let \(v \in V(G)\) be the least vertex with respect to the fixed vertex enumeration that is not already contained in \(V(A^n \cup B^n)\). We know by our construction that either \(V(a_n) <_T V(v)\) or \(V(v) >_T V(a_n)\) for every vertex \(x \in V(A^n \cup B^n)\). Consider the second case, since the argument for the first works analogously. Let \(v' \in V(G)\) be a vertex such that \(V(v)\) is the predecessor of \(V(v)\) with respect to \(\leq_T\) and \(w \in V(G)\) be a vertex such that \(V(w) >_T V(a_n)\) and \(V(w)\) is the successor of either \(V(a_n)\) or \(V(b_n)\), say \(V(b_n)\). By Lemma 3.4 there exists a \(v'\)-\(w\) path \(P\) in \(G[b_n, v]\). We may assume that \(E(P) \setminus E(T)\) does not contain an edge whose endvertices lie in the same graph-theoretical component of \(T\) and that every graph-theoretical component of \(T\) is incident with at most two edges of \(E(P) \setminus E(T)\). Otherwise we could use square strings to reduce the situation to the assumptions we made.
Next we inductively define a finite sequence of finite Eulerian auxiliary multi-
graphs $H_1, \ldots, H_k$ for some $k \in \mathbb{N}$ where every vertex has either degree 2 or 4 in
each of these multigraphs and we obtain $H_{i+1}$ from $H_i$ as a $h$-split for some vertex
$h \in V(H_i)$ of degree 4 until we end up with a multigraph $H_k$ that is a cycle.

As $V(H_1)$ take the set of all graph-theoretical components $T_1, \ldots, T_n$ of $T$ that
are incident with an edge of $E(P) \setminus E(T)$. Two vertices $T_i$ and $T_j$ are adjacent if
either there is an edge in $E(P) \setminus E(T)$ whose endpoints lie in $T_i$ and $T_j$ or there is a
transition arc $t_i \sim t_j$ in $\mathcal{T}$ for a subgraph $A$ of $T$ and vertices $t_i \in V(T_i)$ and $t_j \in V(T_j)$ such
that no endvertex of any edge of $E(P) \setminus E(T)$ lies in $V(A) \cup N_T(A)$. Since $\mathcal{T}$ is a
topological spanning caterpillar, the multigraph $H_1$ is connected and by definition of $P$ it is also Eulerian where all vertices have either degree 2 or 4.

Now suppose we have already constructed $H_i$ and there exists a vertex $h \in V(H_i)$
with degree 4 in $H_i$. Since $H_i$ is obtained from $H_1$ via repeated splitting operations,
we know that $h$ is incident with two edges $d, e$ in $H_i$ that correspond to edges $d_P, e_P$ of
$E(P) \setminus E(T)$ and with two edges $f, g$ that correspond to arcs $h_f$ and $h_g$, respectively,
of $\mathcal{T}$ for subgraphs $A_f$ and $A_g$ of $T$ such that neither $V(A_f) \cup N_T(A_f)$ nor
$V(A_g) \cup N_T(A_g)$ contain an endvertex of an edge of $E(P) \setminus E(T)$. Let $H_j$ be the
graph-theoretical component of $T$ in each of which $d_P$ and $e_P$ has an endvertex,
say $w_d$ and $w_e$, respectively. Here we consider two cases:

**Case 1. The distance in $T_j$ between $w_d$ and $w_e$ is even.**

In this case we define $H_{i+1}$ as a Eulerian $h$-split of $H_i$ such that the edge in $H_{i+1}$
corresponding to $d$ is either adjacent to the one corresponding to $e$ or the one
not corresponding to either $f$ or $g$ with the property that the path in $T_j$ connecting $w_d$
and $A_f$ (resp. $A_g$) does not contain $w_e$. This is possible since two of the three
possible non-isomorphic $h$-splittings of $H_i$ are Eulerian by Lemma 3.7.

**Case 2. The distance in $T_j$ between $w_d$ and $w_e$ is odd.**

Here we set $H_{i+1}$ as a Eulerian $h$-split of $H_i$ such that the edge in $H_{i+1}$
corresponding to $d$ is not adjacent to the one corresponding to $e$. As in the first case,
this is possible because two of the three possible non-isomorphic $h$-splittings of $H_i$ are
Eulerian by Lemma 3.7. This completes the definition of the sequence of auxiliary
multi-graphs.

Now we use the last auxiliary multigraph $H_k$ of the sequence to define the arcs
$A^n_{k+1}$ and $B^n_{k+1}$. Note that $P$ is a $w \to v'$ path in $G[I_{b^n_w, v}]$ where $v'$ and $w$
lie in the same graph-theoretical components $T_v$ and $T_w$ of $T$ as $v$ and $b^n_w$, respectively.
Since we may assume that $E(P) \setminus E(T) \neq \emptyset$ holds, let $e \in E(P) \setminus E(T)$ denote
the edge which contains one endvertex $w_e$ in $T_w$. Then either the distance between
$w_e$ and $a^n_w$ or between $w_e$ and $b^n_w$ is even, say the latter one holds. Now we first
extend $B_w$ via a $[b^n_w, w_e]$ square string in $T^2$ and $A^n$ by a $[a^n_w, v']$ square string
in $T^2$ where $V_{w_e^+}$ is the successor of $V_{w_e}$ with respect to $\leq_T$ and $w_e^+$ is the jumping
vertex of $V_{w_e^+}$. Then we further extend $A^n$ using a ray to contain all vertices of
partition classes $V_x$ with $V_x \succ_T V_{w_e^+}$ for $x \in T_v$. This is possible by Lemma 3.4.

Next let $P_1$ and $P_2$ be the two edge-disjoint $T_v \to T_w$ paths in $H_k$. Since every
edge of $E(P) \setminus E(T)$ corresponds to an edge of $H_k$, we get that $e$ corresponds
either to $P_1$ or $P_2$, say to the former one. Therefore, we will use $P_1$ to obtain
arcs to extend $B^n$ and $P_2$ for arcs extending $A^n$. The way we have defined $H_k$
via splittings ensures that for any vertex $T_j$ of $H_1$ of degree 4 we have performed
a $T_j$-split such that the partition of the edges incident with $T_j$ into pairs of edges
incident with a replacement vertex of $T_j$ corresponds to a decomposition of $T_j$ as in
Lemma 3.5. So for every vertex of $H_1$ of degree 4 we take such a decomposition. For
every graph-theoretical component $T_m$ of $T$ such that there exist two consecutive
edges $T_i T_j$ and $T_j T_\ell$ of $P_1$ or $P_2$ that do not correspond to edges of $E(P) \setminus E(T)$ and $V_{t_i} < T V_{t_m} < T V_{t_j}$ or $V_{t_j} < T V_{t_m} < T V_{t_i}$ holds for every choice of $t_i \in T_i$, $t_j \in T_j$, $t_\ell \in T_\ell$ and $t_m \in T_m$, we take a spanning double ray of $T_m^2$. We can find such spanning double rays using Lemma 3.7. Since $H_e = P_1 \cup P_2$ is a cycle, we can use these decompositions and double rays to extend $\overline{A^n}$ and $\overline{B^{n+1}}$ to be disjoint arcs $\alpha^n$ and $\beta^n$ with endvertices on $T_{v'}$. With the same construction that we have used for extending $A^n$ and $B^n$ on $T_w$, we can extend $\alpha^n$ and $\beta^n$ to have endvertices $v_j'$ and $v_j$ which are the jumping vertices of $V_{v'}$ and $V_v$, respectively, and containing all vertices of partition classes $V_y$ for $y \in T_{v'}$ and $V_y \leq V_v$. Then we take these arcs as $\overline{A^{n+1}}$ and $\overline{B^{n+1}}$ where $A^{n+1}$ and $B^{n+1}$ are the corresponding subgraphs of $G^2$ whose closures give the arcs. By setting $a^n_{v'}$ and $b^{n+1}_{v_j}$ to be $v_j'$ and $v_j$, depending on which of the two arcs $\overline{A^{n+1}}$ or $\overline{B^{n+1}}$ ends in these vertices, we have guaranteed all properties from (1) to (5) for the construction.

Now the properties (3) – (5) yield not only that $\overline{A}$ and $\overline{B}$ are disjoint arcs for $A = \bigcup_{e \in E} A_e$ and $B = \bigcup_{e \in E} B_e$, but also that $V(G) = V(A \cup B)$. If there exists neither a maximal nor minimal partition class with respect to $\leq_T$, the union $\overline{A} \cup \overline{B}$ forms a Hamilton circle of $G^2$ by Lemma 2.7. Should there exist a maximal partition class, say $V_{a_p^r}$ for some $n \in \mathbb{N}$ with jumping vertex $a_p^n$, the vertex $a_p^n$ will also be an endvertex of $\overline{A}$. In this case we connect the endvertices $a_p^n$ and $b_{p}^n$ of $\overline{A}$ and $\overline{B}$ via an edge. Such an edge exists since $V_{a_p^n}$ and $V_{b_p^n}$ are consecutive with respect to $\leq_T$ by property (2) and $a_p^n$ as well as $b_{p}^n$ are jumping vertices by property (1). Analogously, we add an edge if there exists a minimal partition class. Therefore, we can always obtain the desired Hamilton circle of $G^2$.

4. Graphs without $K^4$ or $K_{2,3}$ as minor

We begin this section with a small observation which allows to strengthen Theorem 1.8 a bit by forbidding subgraphs isomorphic to a $K^4$ instead of minors.

**Lemma 4.1.** For graphs without $K_{2,3}$ as a minor it is equivalent to contain a $K^4$ as a minor or as a subgraph.

**Proof.** One implication is clear. So suppose for a contradiction, we have a graph without a $K_{2,3}$ as a minor that does not contain $K^4$ as a subgraph but as a subdivision, which is equivalent to containing a $K^4$ as a minor since $K^4$ is cubic. Consider a subdivided $K^4$ where at least one edge $e$ of the $K^4$ corresponds to a path $P_e$ in the subdivision whose length is at least two. Let $v$ be an interior vertex of $P_e$ and $a, b$ be the endvertices of $P_e$. Let the other two branch vertices of the subdivision of $K^4$ be called $c$ and $d$. Now we take $\{a, b, c, d, v\}$ as branch vertex set of a subdivision of $K_{2,3}$. The vertices $a$ and $b$ can be joined to $c$ and $d$ by internally disjoint paths using the ones of the subdivision of $K^4$ except the path $P_e$. Furthermore, the vertex $v$ can be joined to $a$ and $b$ using the paths $vP_e a$ and $vP_e b$. So we can find a subdivision of $K_{2,3}$ in the whole graph, which contradicts our assumption.

Before we start with the proof of Theorem 1.8 we need to prepare two structural lemmas. The first one will be very convenient to control end degrees because it bounds the size of certain separators.

**Lemma 4.2.** Let $G$ be a 2-connected graph without $K_{2,3}$ as a minor and $K_0$ be a connected subgraph of $G$. Then $|N(K_1)| = 2$ holds for every component $K_1$ of $G - (K_0 \cup N(K_0))$.

**Proof.** Let $K_0$, $G$ and $K_1$ be defined as in the statement of the lemma. Since $G$ is 2-connected, we know that $|N(K_1)| \geq 2$ holds. Now suppose for a contradiction that $N(K_1) \subseteq N(K_0)$ contains three vertices, say $u, v$ and $w$. Pick neighbours $u_i, v_i$
and $w_i$ of $u, v$ and $w$, respectively, in $K_i$ for $i \in \{0, 1\}$. Furthermore, take a finite tree $T_i$ in $K_i$ whose leaves are precisely $u_i, v_i$ and $w_i$ for $i \in \{0, 1\}$. This is possible because $K_0$ and $K_1$ are connected. Now we have a contradiction since the graph $H$ with $V(H) = \{u, v, w\} \cup V(T_0) \cup V(T_1)$ and $E(H) = \bigcup_{i=0}^1(\{u_i, v_i, w_i\} \cup E(T_i))$ forms a subdivision of $K_{2,3}$. □

For a connected graph $G$ with a subgraph $K$ let $G_K$ denote the graph which is formed by taking $G$ and contracting all components of $G - K$ where we delete multiple edges or loops. Obviously $G_K$ is connected if $G$ was connected. We can push this observation a bit further towards 2-connectedness with the following lemma.

Lemma 4.3. Let $K$ be a connected subgraph with at least three vertices of a 2-connected graph $G$. Then $G_K$ is 2-connected.

Proof. Suppose for a contradiction that $G_K$ is not 2-connected for some $G$ and $K$ as in the statement of the lemma. Since $K$ has at least three vertices, we obtain that $G_K$ has at least three vertices too. So there exists a cut vertex $v$ in $G_K$. If $v$ is also a vertex of $G$ and therefore does not correspond to a contracted component of $G - K$, then $v$ would also be a cut vertex of $G$, which contradicts the assumption that $G$ is 2-connected.

Otherwise $v$ corresponds to a contracted component of $G - K$. Since vertices of $G_K$ that correspond to contracted components of $G - K$ are not adjacent by definition of $G_K$ and $v$, as a cut vertex in $G_K$, must have at least one neighbour in each component of $G_K - v$, we get in particular that $v$ separates two vertices, say $x$ and $y$, of $G_K$ that do not correspond to contracted components of $G - K$. This yields a contradiction because $K$ is connected and therefore contains an $x$-$y$ path, which still exists in $G_K$ and contradicts the statement that $v$ separates $x$ and $y$ in $G_K$. □

With the lemmas above we are now prepared to prove Theorem 1.8.

Proof of Theorem 1.8. First we show that (ii) implies (i). Since $G$ is Hamiltonian, we know by Corollary 2.8 that $G$ is 2-connected. Suppose for a contradiction that $G$ contains $K^4$ or $K_{2,3}$ as a minor. Then $G$ has a finite subgraph $H$ which already has $K^4$ or $K_{2,3}$ as a minor. Now take any finite connected subgraph $K_0$ of $G$ which contains $H$ and set $K = G[V(K_0) \cup N(K_0)]$. Next let us take an embedding of $|G|$ as in statement (ii) of this theorem. It is easy to see using Lemma 1.2 that our fixed embedding of $|G|$ induces an embedding of $G_K$ into a closed disk such that all vertices of $G_K$ lie on the boundary of the disk. This implies that $G_K$ is outerplanar. So $G_K$ can neither contain $K^4$ nor $K_{2,3}$ as a minor by Theorem 1.7 which contradicts that $H$ is a subgraph of $G_K$.

Now let us assume (i) to prove the remaining implication. We set $K_0$ as an arbitrary connected subgraph of $G$ with at least three vertices. Next we define $K_{i+1} = G[V(K_i) \cup N(K_i)]$ for every $i \geq 0$. By Lemma 4.3 we know that $G_{K_i}$ is 2-connected for each $i \geq 0$. Furthermore, $G_{K_i}$ contains neither $K^4$ nor $K_{2,3}$ as a minor for every $i \geq 0$ since it would also be a minor of $G$ contradicting our assumption. So each $G_{K_i}$ is outerplanar by Theorem 1.7. Using statement (ii) of Proposition 1.6 we obtain that each $G_{K_i}$ has a unique Hamilton cycle $C_i$ and that there is an embedding $\sigma_i$ of $G_{K_i}$ into a fixed closed disk $D$ such that $C_i$ is mapped onto the boundary $\partial D$ of $D$. Set $E_i = E(C_i) \cap E(K_i)$ for every $i \geq 1$.

Next we define an embedding of $G$ into $D$ and extend it to the desired embedding of $|G|$. First take $\sigma_1 |_{K_1}$. Note that $\sigma_1(E_i)$ lies on the boundary $\partial D$ of $D$. Because of Lemma 1.2 we can extend $\sigma_1 |_{K_1}$ using $\sigma_2 |_{K_2 \setminus K_1}$, maybe after rescaling it, to obtain an embedding of $K_2$ such that the image of $E_2$ lies on $\partial D$. Proceeding in
the same way, we get an embedding $\sigma$ of all of $G$ into $D$ by $\sigma_1 |_{K_i}$ together with rescaled embeddings $\sigma_{i+1} |_{K_{i+1}\setminus K_i}$ for every $i \geq 1$ such that all vertices of $G$ are mapped to $\partial D$. Furthermore, we may assume that $\sigma$ has the following property:

Let $(M_i)_{i\geq 1}$ be an infinite sequence of components $M_i$ of $G - K_i$ where $M_{i+1} \subseteq M_i$. Also, let $\{u_i, w_i\}$ be the neighbourhood of $M_i$ in $G$. Then it $(\ast)$ holds that $(\sigma(u_i))_{i\geq 1}$ and $(\sigma(w_i))_{i\geq 1}$ converge to a common point on $\partial D$.

It remains to extend this embedding $\sigma$ to an embedding $\bar{\sigma}$ of all of $|G|$ into $D$. First we shall extend the domain of $\sigma$ to all of $|G|$. For this we need to prove the following claim.

**Claim 1.** For every end $\omega$ of $G$ there exists an infinite sequence $(M_i)_{i\geq 1}$ of components $M_i$ of $G - K_i$ with $M_{i+1} \subseteq M_i$ such that $\bigcap_{i\geq 1} M_i = \{\omega\}$.

Since $K_i$ is finite, there exists a unique component of $G - K_i$ in which all $\omega$-rays have a tail. Set this component as $M_i$. It follows from the definition that $\omega$ lies in $M_i$. Furthermore, we get that $\bigcap_{i\geq 1} M_i$ does neither contain any vertex nor an inner point of any edge. So suppose for a contradiction that $\bigcap_{i\geq 1} M_i$ contains another end $\omega' \neq \omega$. We know there exists a finite set $S$ of vertices such that all tails of $\omega'$-rays lie in a different component of $G - S$ than all tails of $\omega$-rays. By definition of the graphs $K_i$ we can find an index $j$ such that $S \subseteq V(K_j)$. So $\omega$ lies in $M_j$ and $\omega'$ in $M_j'$ where $M_j'$ is the component of $G - K_j$ in which all tails of $\omega$-rays lie. Since $G$ is locally finite, the cut $E(M_j, K_j)$ is finite. Using Lemma 2.3 we obtain that $M_j \cap M_j' = \emptyset$. Therefore, $\omega' \notin M_j \supseteq \bigcap_{i\geq 1} M_i$. This contradiction completes the proof of the claim.

Now let us define the map $\bar{\sigma}$. For every vertex or inner point of an edge $x$, we set $\bar{\sigma}(x) = \sigma(x)$. For an end $\omega$ let $(M_i)_{i\geq 1}$ be the sequence of components $M_i$ of $G - K_i$ given by Claim 1 and $\{u_i, w_i\}$ be the neighbourhood of $M_i$ in $G$. Using property $(\ast)$ we know that $(\sigma(u_i))_{i\geq 1}$ and $(\sigma(w_i))_{i\geq 1}$ converge to a common point $p_\omega$ on $\partial D$. We use this to set $\bar{\sigma}(\omega) = p_\omega$. This completes the definition of $\bar{\sigma}$.

Next we prove the continuity of $\bar{\sigma}$. For every vertex or inner point of an edge $x$, it is easy to see that an open set around $\bar{\sigma}(x)$ in $D$ contains $\bar{\sigma}(U)$ for some open set $U$ around $x$ in $|G|$ because $G$ is locally finite and so it follows from the definition of $\bar{\sigma}$ using the embeddings $\sigma_i$. Let us check continuity for ends. Consider an open set $O$ around $\bar{\sigma}(\omega)$ in $D$, where $\omega$ is an end of $G$. Let $(M_i)_{i\geq 1}$ be a sequence as in Claim 1 for $\omega$ and $\{u_i, w_i\}$ be the neighbourhood of $M_i$ in $G$. By property $(\ast)$ and the definition of $\bar{\sigma}$, we get that $(\sigma(u_i))_{i\geq 1}$ and $(\sigma(w_i))_{i\geq 1}$ converge to $\bar{\sigma}(\omega)$ on $\partial D$. So there exists a $j$ such that $O$ contains $\sigma(u_i)$ and $\sigma(w_i)$ for every $i \geq j$. By the definition of $\bar{\sigma}$ and $\sigma$ using the embeddings $\sigma_i$, it follows that $\bar{\sigma}(M_j) \subseteq O$. Since $M_j$ together with the inner points of the edges of $E(M_j, K_j)$ is a basic open set in $|G|$ containing $\omega$ whose image under $\bar{\sigma}$ is contained in $O$, continuity holds for ends too.

The next step is to check that $\bar{\sigma}$ is injective. If $x$ and $y$ are each either a vertex or an inner point of an edge, then they already lie in some $K_j$. By the definition of $\bar{\sigma}$ we get that $\bar{\sigma}(x) = \bar{\sigma}(y)$ if and only if there exists a $j$ such that $x$ and $y$ are mapped to the same point by the embedding of $K_j$ defined by $\sigma_1 |_{K_j}$ and $\sigma_{i+1} |_{K_{i+1}\setminus K_i}$ for every $i$ with $1 \leq i \leq j - 1$. So $x$ and $y$ need to be equal.

For an end $\omega$ of $G$, let $(M_i)_{i\geq 1}$ be a sequence of components of $G - K_i$ such that $\bigcap_{i\geq 1} M_i = \{\omega\}$, which exists by Claim 1, and $\{u_i, w_i\}$ be the neighbourhood of $M_i$ in $G$. Since $G$ is locally finite, there exists an integer $j$ such that $y$ lies in $K_j$ if it is a vertex or an inner point of an edge, or $y$ lies in $M_i$ for some component $M_i' \neq M_j$ of $G - K_j$ if $y$ is an end of $G$. By the definition of $\bar{\sigma}$ and property $(\ast)$ we
get that the arc on \( \partial D \) between \( \sigma(u_j) \) and \( \sigma(w_j) \) into which the vertices of \( M_i \) are mapped contains also \( \overline{\sigma}(\omega) \) but not \( y \). Hence, \( \overline{\sigma}(\omega) \neq \overline{\sigma}(y) \) if \( \omega \neq y \). This shows the injectivity of the map \( \overline{\sigma} \).

To see that \( \overline{\sigma}^{-1} \) is continuous, note that \( |G| \) is compact by Proposition 2.1 and \( D \) is Hausdorff. So Lemma 2.2 immediately implies that \( \overline{\sigma}^{-1} \) is continuous. This completes the proof that \( \overline{\sigma} \) is an embedding.

It remains to show the existence of a unique Hamilton circle of \( G \) that is mapped onto \( \partial D \) by \( \overline{\sigma} \). For this we first prove that \( \partial D \subseteq \text{Im}(\overline{\sigma}) \). This then implies that \( \overline{\sigma}^{-1} \upharpoonright \partial D \) is a homeomorphism defining a Hamilton circle of \( G \) since it contains all vertices of \( G \). We begin by proving the following claim.

**Claim 2.** For every infinite sequence \((M_i)_{i \geq 1}\) of components \( M_i \) of \( G - K_i \) with \( M_{i+1} \subseteq M_i \), there exists an end \( \omega \) of \( G \) such that \( \bigcap_{i \geq 1} \overline{M_i} = \{ \omega \} \).

Let \((M_i)_{i \geq 1}\) be any sequence as in the statement of the claim. Since for every vertex \( v \) there exists a \( j \in \mathbb{N} \) such that \( v \in K_j \), we get that \( \bigcap_{i \geq 1} \overline{M_i} \) is either empty or contains ends of \( G \). Using that each \( M_i \) is connected and that \( M_{i+1} \subseteq M_i \), we can find a ray \( R \) such that in every \( M_i \) lies a tail of \( R \). Therefore, \( \bigcap_{i \geq 1} \overline{M_i} \) contains the end in which \( R \) lies. The argument that \( \bigcap_{i \geq 1} \overline{M_i} \) contains at most one end is the same as in the proof of Claim 1. This completes the proof of Claim 2.

Suppose a point \( p \in \partial D \) does not already lie in \( \text{Im}(\sigma) \). Then it does neither lie in \( \text{Im}(\sigma_1 \upharpoonright [K_i]) \) nor in any \( \text{Im}(\sigma_{i+1} \upharpoonright [K_{i+1}\setminus K_i]) \). So there exists an infinite sequence \((M_i)_{i \geq 1}\) of components \( M_i \) of \( G - K_i \) with \( M_{i+1} \subseteq M_i \) such that \( p \) lies in the arc \( A_i \) of \( \partial D \) between \( \sigma(u_i) \) and \( \sigma(w_i) \) into which the vertices of \( M_i \) are mapped, where \( \{u_i, w_i\} \) denotes the neighbourhood of \( M_i \) in \( G \). Using Claim 2 we obtain that there exists an end \( \omega \) of \( G \) such that \( \bigcap_{i \geq 1} \overline{M_i} = \{ \omega \} \). By property \((*)\) of the map \( \sigma \) the sequences \( (\sigma(u_i))_{i \geq 1} \) and \( (\sigma(w_i))_{i \geq 1} \) converge to a common point on \( \partial D \), which must be \( p \) since the arcs \( A_i \) are nested. Now the definition of \( \overline{\sigma} \) tells us that \( \overline{\sigma}(\omega) = p \). Hence \( \partial D \subseteq \text{Im}(\overline{\sigma}) \) and \( G \) is Hamiltonian.

We finish the proof by showing the uniqueness of the Hamilton circle of \( G \). Suppose for a contradiction that \( G \) has two subgraphs \( C_1 \) and \( C_2 \) yielding different Hamilton circles \( \mathcal{C}_1 \) and \( \mathcal{C}_2 \). Then there must be an edge \( e \in \overline{E}(C_1) \setminus \overline{E}(C_2) \). Let \( j \in \mathbb{N} \) be chosen such that \( e \in \overline{E}(K_j) \). By Lemma 4.2 we obtain that \( G_{K_j}[\overline{E}(C_1) \cap \overline{E}(G_{K_j})] \) and \( G_{K_j}[\overline{E}(C_2) \cap \overline{E}(G_{K_j})] \) are two Hamilton cycles of \( G_{K_j} \) differing in the edge \( e \). Note that \( G_{K_j} \) is a finite 2-connected outerplanar graph. The argument for this is the same as for \( G_K \) in the proof that \((ii)\) implies \((i)\). This yields a contradiction since \( G_{K_j} \) has a unique Hamilton cycle by statement \((ii)\) of Proposition 1.6.

Next we deduce Corollary 1.9.

**Proof of Corollary 1.9.** Let \( G \) be a locally finite 2-connected graph not isomorphic to a \( K^4 \) and not containing \( K_{2,3} \) as a minor. Further, let \( C \) be the subgraph of \( G \) such that \( \overline{C} \) is the Hamilton circle of \( G \). First we show that each edge \( e \in \overline{E}(C) \) is a 2-contraction edge. Note for this that the closure of the subgraph of \( G/e \) formed by the edge set \( \overline{E}(C) \setminus \{e\} \) is a Hamilton circle in \( \overline{G/e} \). Hence, \( G/e \) is 2-connected by Corollary 2.8.

It remains to verify that no edge of \( \overline{E}(G) \setminus \overline{E}(C) \) is 2-contraction. For this we consider any edge \( e = uv \in \overline{E}(G) \setminus \overline{E}(C) \). Let \( K \) be a finite connected induced subgraph of \( G \) containing at least four vertices as well as \( N(u) \cup N(v) \), which is a finite set since \( G \) is locally finite. Then we know by Lemma 4.3 and by using the locally finiteness of \( G \) again that \( G_K \) is a finite 2-connected graph not containing \( K^4 \) or \( K_{2,3} \) as a minor. So by Theorem 1.7 and Proposition 1.6 we get that \( G_K \) has
a unique Hamilton cycle consisting precisely of its 2-contractible edges. However, as we have seen in the proof of Theorem 1.8, $G_K[E(C) \cap E(G_K)]$ is then the unique Hamilton cycle of $G_K$ and it does not contain $e$. Since $G_K$ is outerplanar, we get that the vertex of $G_K/e$ corresponding to the edge $e$ is a cut vertex in $G_K/e$. By our choice of $K$ containing $N(u) \cup N(v)$, we get that the vertex in $G/e$ corresponding to the edge $e$ is a cut vertex of $G/e$ too. So $e$ is not 2-contractible.

The question arises whether one could prove the more complicated part of Theorem 1.8, the implication $(i) \implies (ii)$, by mimicking a proof for finite graphs. To see the positive answer for this question, let us summarize the proof for finite graphs except the part about the uniqueness.

By Theorem 1.7 every finite graph without $K_4$ or $K_{2,3}$ as a minor can be embedded into the plane such that all vertices lie on a common face boundary. Since every face of an embedded 2-connected graph is bounded by a cycle, we obtain the desired Hamilton cycle.

So for our purpose we would first need to prove a version of Theorem 1.7 for $|G|$ where $G$ is a locally finite graph. This can be done similar to the way we have defined the embedding for the Hamilton circle in Theorem 1.8 by decomposing the graph into finite parts using Lemma 4.2. Since none of these parts contains a $K_4$ or a $K_{2,3}$ as a minor, we can fix appropriate embeddings of them and stick them together. In order to obtain an embedding of $|G|$, we need furthermore to ensure that the embeddings of finite parts that converge to an end in $|G|$ also converge to a point in the plane where we can map the corresponding end to.

The second ingredient of the proof is the following lemma pointed out by Bruhn and Stein, but which is a corollary of a stronger and more general result of Richter and Thomassen [23, Prop. 3].

Lemma 4.4. [2, Cor. 21] Let $G$ be a locally finite 2-connected graph with an embedding $\varphi : |G| \to S^2$. Then the face boundaries of $\varphi(|G|)$ are circles of $|G|$. These observations show that the proof idea for finite graphs is still applicable for locally finite graphs.

5. A cubic infinite graph with a unique Hamilton circle

This section is dedicated to Theorem 1.11 by constructing an infinite graph with a unique Hamilton circle where all vertices and ends of the graph have degree or vertex- as well as edge-degree 3, respectively. The main ingredient in our construction is a finite graph $T$ for which we know where all Hamilton paths, i.e., spanning paths, proceed after deleting certain vertices. This graph has been used by Tutte [30] to construct a counterexample to Tait’s conjecture [27], which said that every 3-connected cubic planar graph is Hamiltonian. The following lemma captures the facts about $T$ we shall need. The proof is straightforward, but involves several cases that need to be distinguished.

Lemma 5.1. There is no Hamilton path in $T - u$, but there are precisely two in $T - r$ (see Figure 4).

Proof. As mentioned already by Tutte [30], the graph $T - u$ does not have a Hamilton path. It remains to show that $T - r$ has precisely two Hamilton paths. For this we need to check several cases, but afterwards we can precisely state the Hamilton paths. For convenience, we label each edge with a number as depicted in Figure 5 and refer to the edges just by their labels for the rest of the proof.

Obviously, the edges incident with $\ell$ and $u$ would need to be in every Hamilton path of $T - r$ since these vertices have degree 1. Furthermore, the edges 2 and 3
need to be in every Hamilton path of $T - r$ since the vertex incident with 2 and 3 has degree 2 in $T - r$.

**Claim 3.** The edge 4 needs to be in every Hamilton path of $T - r$.

Suppose for a contradiction that there is a Hamilton path $P$ in $T - r$ that does not use 4. Then it needs to contain 1. Since it also contains 2, we know $5 \notin E(P)$. This implies further that $7, 8 \in E(P)$. We can use $4 \notin E(P)$ also to deduce that $6, 10 \in E(P)$ holds. Now we get $11 \notin E(P)$ since $6, 7 \in E(P)$. This implies $20, 21 \in E(P)$. But now $14 \notin E(P)$ holds because $10, 20 \in E(P)$. From this we get then $16, 18 \in E(P)$. So 19 cannot be contained in $P$, which implies $13, 17 \in E(P)$. Now we arrived at a contradiction since the edges incident with $l$ and $u$ together with the edges of the set $\{1, 2, 3, 13, 17, 16, 18\}$ form a $l$-$u$ path in $T - r$ that is contained in $P$ and needs therefore to be equal to $P$. Then, however, $P$ would not be a Hamilton path $T - r$. This completes the proof of Claim 3.

We immediately get from Claim 3 that 5 needs to be in every Hamilton path of $T - r$ and since 8 and 9 cannot both be contained in any Hamilton path of $T - r$, because they would close a cycle together with 5, 2 and 3, we also know that 12 needs to be in every Hamilton path of $T - r$.

**Claim 4.** The edges 14 and 16 lie in every Hamilton path of $T - r$. 
Suppose for a contradiction that the claim is not true. Then there is a Hamilton path $P$ of $T - r$ containing 18. So $P$ cannot contain 19, which implies $13, 17 \in E(P)$. Since $3, 13 \in E(P)$, we obtain $9 \notin E(P)$, from which we follow that $8 \in P$ holds. Furthermore, 15 cannot be contained in $P$, because then the edges $15, 17, 13, 2, 5, 8, 12$ would form a cycle in $P$. Therefore, 16 is an edge of $P$. From $5, 8 \in E(P)$ we can deduce that $7 \notin E(P)$ holds. So 6 and 11 are edges of $P$, which that implies $10 \notin E(P)$. Then $14, 20 \in E(P)$ needs to be true. Now, however, we have a contradiction, because $P$ would have a vertex incident with three vertices, namely 14, 16 and 18. This completes the proof of Claim 4.

It follows from Claim 4 that 19 is contained in every Hamilton path of $T - r$. We continue with another claim.

**Claim 5.** The edges 6 and 20 lie in every Hamilton path of $T - r$.

Suppose for a contradiction that the claim is not true. Then there is a Hamilton path $P$ of $T - r$ containing 10. This immediately implies that $6 \notin E(P)$, yielding $7, 11 \in E(P)$, and $20 \notin E(P)$, yielding $21 \in E(P)$. We note that 8 cannot be an edge of $P$ since $P$ would then contain a cycle spanned by the edge set $\{8, 7, 11, 21, 12\}$. Therefore, $9 \in E(P)$ must hold. Here we arrive at a contradiction, since $P$ now contains a cycle spanned by the edge set $\{9, 3, 2, 5, 7, 11, 21, 12\}$. This completes the proof of Claim 5.

Using all the observations we have made so far, we can now show that $T - r$ has precisely two Hamilton paths and state them by looking at the edge 11. Assume that 11 is contained in a Hamilton path $P_1$ of $T - r$. Then $7, 21 \notin E(P_1)$ follows, because $6, 20 \in E(P_1)$ holds by Claim 5. Since we could deduce from Claim 3 that $5, 12 \in E(P_1)$ holds, we get furthermore $8, 15 \in E(P_1)$. This now yields $9, 17 \notin E(P_1)$ and, therefore, $13 \in E(P_1)$. As we can see, the assumption that 11 is contained in a Hamilton path $P_1$ of $T - r$ is true. Also, $P_1$ is uniquely determined with respect to this property and consists of the fat edges in the most right picture of Figure 3.

Next assume that there is a Hamilton path $P_2$ of $T - r$ that does not contain the edge 11. Then 7 and 21 have to be edges of $P_2$. Using again that $5, 12 \in E(P_2)$ holds, we deduce $8, 15 \notin E(P_2)$. Then, however, we get $9, 17 \in E(P)$ and have already uniquely determined $P_2$, which corresponds to the fat edges in the middle picture of Figure 3. □

Using Lemma 5.1 we will now prove Theorem 1.11 by constructing a prescribed graph.

**Proof of Theorem 1.11.** We construct a sequence of graphs $(G_n)_{n \in \mathbb{N}}$ inductively and obtain the desired one $G$ as a limit of the sequence. We start with $G_0 = T_0 = T$.

Now suppose we have already constructed $G_n$ for $n \geq 0$. Furthermore, let $\{T_n^i : 1 \leq i \leq 2^n\}$ be a specified set of disjoint subgraphs of $G_n$ each of which each is isomorphic to $T$. We define $G_{n+1}$ as follows. Take $G_n$ and two copies $T_c$ and $T_v$ of $T$ for each $T_n^i \subseteq G_n$. Then identify for every $i$ the vertices of $T_n$ that correspond to $u$, $\ell$ and $r$, respectively, with the vertices of the related $T_n^i \subseteq G_n$ corresponding to $\ell$, $s$ and $t$, respectively. Also identify for every $i$ the vertices of $T_v$ corresponding to $u$, $\ell$ and $r$, respectively, with the ones of the related $T_n^i \subseteq G_n$ corresponding to $w$, $x$ and $y$, respectively. Finally, delete in each $T_n^i \subseteq G_n$ the vertices corresponding to $c$ and $v$, see Figure 6. This completes the definition of $G_{n+1}$. It remains to fix the set of $2^{n+1}$ many disjoint copies of $T$ that occur as disjoint subgraphs in $G_{n+1}$. For this we take the set of all copies $T_c$ and $T_v$ of $T$ that we have inserted in the subgraphs $T_n^i$ of $G_n$. 
Using the graphs $G_n$ we define a graph $\hat{G}$ as a limit of them. We set

$$\hat{G} = G[\hat{E}] \text{ where } \hat{E} = \left\{ e \in \bigcup_{n \in \mathbb{N}} E(G_n) : \exists N \in \mathbb{N} : e \in \bigcap_{n \geq N} E(G_n) \right\}.$$

Note that an edge $e \in E(G_n)$ is an element of $\hat{E}$ if and only if it was not deleted during the construction of $G_{n+1}$ as an edge incident with one of the vertices that correspond to $v$ or $w$ in $T_i^n$ for some $i$. Finally we define $G$ as the graph obtained from $\hat{G}$ by identifying the three vertices that correspond to $u$, $\ell$ and $r$ of $T_i^n$.

Next let us verify that every vertex and every end of $G$ has degree or vertex-degree, respectively, 3. Since every vertex of $T$ except $u$, $\ell$ and $r$ has degree 3, the construction ensures that every vertex of $G$ has degree 3 too. In order to analyse the end degrees, we have to make some observations first. The edges of $G$ that are adjacent to vertices corresponding to $u$, $\ell$ and $r$ of any $T_i^n$ define a cut $E(A_{\ell}^n, B_i^n)$ of $G$. Note that for any finite cut of a graph all rays in one end of the graph have tails that lie completely on one side of the cut. Therefore, the construction of $G$ ensures that for every end $\omega$ of $G$ there exists a function $f : \mathbb{N} \rightarrow \mathbb{N}$ with $f(n) \in \{1, \ldots, 2^n\}$ such that all rays in $\omega$ have tails in $B_i^n(f(n))$ for each $n \in \mathbb{N}$ and $B_i^n(f(n)) \supseteq B_i^{n+1}$ with $\bigcap_{n \in \mathbb{N}} B_i^{f(n)} = \emptyset$. Using that $|E(A_{\ell}^n, B_i^n)| = 3$ for every $n$ and $i$, this implies that every end of $G$ has edge-degree at most 3. Since there are three disjoint paths from $\{u, \ell, r\}$ to $\{s, t, i\}$ as well as to $\{x, w, y\}$ in $T_i$, we can also easily construct three disjoint rays along the cuts $E(A_{\ell}^n, B_i^n)$ that belong to an arbitrary chosen end of $G$. So every end of $G$ has vertex-degree 3. In total this yields that every end of $G$ has vertex- as well as edge-degree 3.

It remains to prove that $G$ has precisely one Hamilton circle. We begin by stating the edge set of the subgraph $C$ defining the Hamilton circle $\overline{C}$ of $G$. Let $E(C)$ consist of those edges of $E(G) \cap T_i^n$ for every $n$ and $i$ that correspond to the fat edges of $T$ in the most right picture of Figure 4. Now consider any finite cut $D$ of $G$.

The construction of $G$ yields that there exists an $N \in \mathbb{N}$ such that $D$ is already a cut of the graph obtained from $G_n$ by identifying the vertices corresponding to $u$, $\ell$ and $r$ of $T_i^n \subseteq G_n$ for all $n \geq N$. Using this observation we can easily see that every vertex of $G$ has degree 2 in $\overline{C}$ and that every finite cut is met at least twice, but always in an even number of edges of $C$. By Lemma 2.5 we get that $\overline{C}$ is topologically and also arc-connected. Therefore, every end of $G$ has edge-degree at least 1 and at most 3 in $\overline{C}$. Together with Theorem 2.6 this implies that every end of $G$ has edge-degree 2 in $\overline{C}$. Hence, Lemma 2.7 tells us that $\overline{C}$ is a circle, which is Hamiltonian since it contains all vertices of $G$.

\textbf{Figure 6.} A sketch of the construction of $G_1$. The fat black, grey and dashed edges incident with the grey vertices in the right picture correspond to the ones in the left picture.
We finish the proof by showing that $\overline{C}$ is the unique Hamilton circle of $G$. Since any Hamilton circle $H$ of $G$ hits each cut $E(A_i^0, B_i^0)$ precisely twice, $H$ induces a path through $T$ that contains all vertices of $T$ except one out of the set $\{u, \ell, r\}$. By Lemma 5.1 we know that such paths must contain the edge adjacent to $u$. Let us consider any $T_n^0$ in $G_n$ and let $T_n^{0+1}$ be the copy of $T$ whose vertices of degree 1 we have identified with the vertices corresponding to the neighbours of $c$ in $T_n$ during the construction of $G_n^{0+1}$. The way we have identified the vertices implies that path induced by $H$ through $T_n^0$ must also use the edge adjacent to $u$. With a similar argument we obtain that the induced path inside $T_n^0$ must use the edge corresponding to $vw$. We know from Lemma 5.1 that there is a unique Hamilton path in $T - r$ that uses the edges $\ell c$ and $vw$, namely the one corresponding to the fat edges in the most right picture of Figure 4. So the edges which must be contained in every Hamilton circle are precisely those of $C$. □
